-----	---	---

Chapter 1

Introduction

– overview of the book, intended audience, getting started (installation instructions etc.)

1.1 Using pyactr – people familiar with Python

If you are familiar with Python, you can install `pyactr` (the Python package that enables ACT-R) and proceed to Chapter 2. `pyactr` is a Python 3 package and can be installed using `pip` (for Python 3):

```
$ pip3 install pyactr
```

1

Alternatively, you can download the package here: <https://github.com/jakdot/pyactr> and follow the instructions there to install the package.

If you are not familiar with Python, you should consider the steps below.

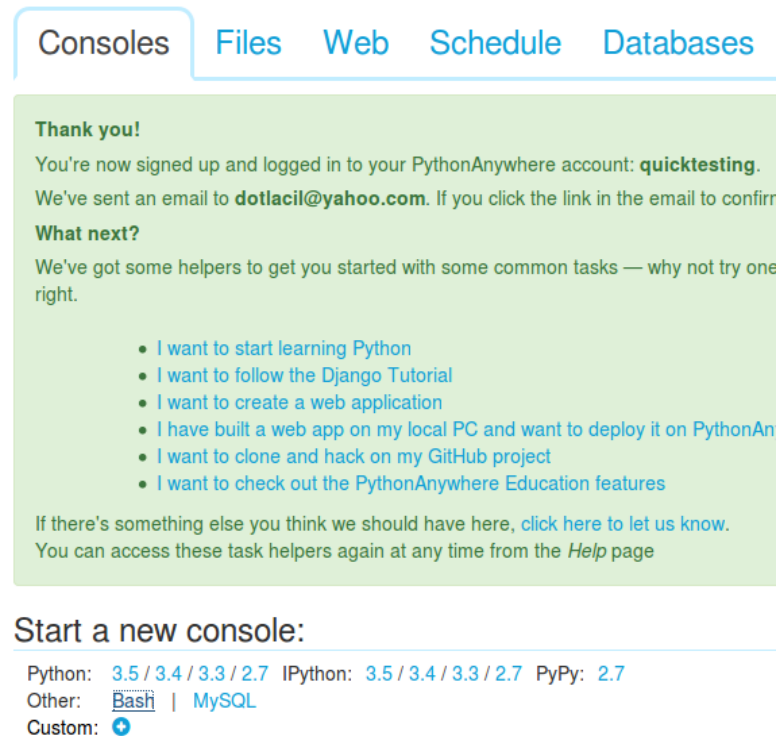

1.2 Using pyactr – beginners

`pyactr` is a package in Python 3. To get started, you should consider a web-based service for Python 3 like PythonAnywhere. In this type of services, computation is hosted on separate servers and you don't have to install anything on your computer (of course, you'll need Internet access). If you find you like working with Python and `pyactr`, you can install them on your computer at a later point together with a good text editor for code – or install an integrated desktop environment (IDE) for Python – a common choice is `anaconda`, which comes with a variety of ways of working interactively with Python (IDE with Spyder as the editor, `ipython` notebooks etc.). But none of this is required to run `pyactr` and the code in this book.

- a. Go to www.pythonanywhere.com and sign up there.
- b. You'll receive a confirmation e-mail. Confirm your account.
- c. Log into your account on www.pythonanywhere.com.

- d. You should see a window like the one below. Click on Bash (below “Start a new Console”).

Figure 1.1: Opening Bash in PythonAnywhere.

- e. In Bash, type:

```
$ pip3 install --user pyactr
```

1

This will install `pyactr` in your Python account (not on your computer).

- f. Go back to Consoles. Start Python by clicking on any version higher than 3.2.
 g. A console should open. Type:

```
import pyactr
```

1

If no errors appear, you are set and can proceed to Chapter 2.

Throughout the book, we will introduce and discuss various ACT-R models coded in Python. You can either type them in line by line or even better, load them as files in your session on PythonAnywhere. Scripts are uploaded under the tab Files. You should be aware that the free account of PythonAnywhere allows you to run only two consoles, and there is a limit on the amount of CPU you might use per day. The limit should suffice for the tutorials but if you find this too constraining, you should consider installing Python (Python 3) and `pyactr` on your computer and running scripts directly there.

Chapter 2

Basics of ACT-R

2.1 Introduction

Adaptive Control of Thought – Rational (ACT-R¹) is a cognitive architecture: it is a theory of the structure of the human mind/brain that explains and predicts human cognition. The ACT-R theory has been implemented in several programming languages, including Java (jACT-R, Java ACT-R), Swift (PRIM), Python2 (ccm). The canonical implementation has been created and is maintained in Lisp. In this book, we will use a novel Python (Python3) implementation (`pyactr`). This implementation is very close to the official implementation in Lisp, so once you learn it you should be able to transfer your skills very quickly to code models in Lisp ACT-R if you wish to do that. At the same time, since Python is currently much more widespread than Lisp and has a much larger and more diverse ecosystem of libraries, coding parts that do not directly pertain to the ACT-R model (like data manipulation / data munging, interactions with the operating system, displaying simulation results, incorporating them into tex / pdf documents etc.) are much better supported than in Lisp. Because of this, the programming language and programming-related issues stand less in the way of learning ACT-R, and you can more fully focus on learning and doing cognitive modeling for linguistic applications and communicating your results, rather than spending a significant amount of time on issues having to do with the computational tools you need to run, examine and evaluate your models.

This book and the cognitive models we build and discuss are not intended as a comprehensive introduction and/or reference manual for ACT-R. For learning the theory behind ACT-R and its main applications in cognitive psychology, consider [Anderson \(1990\)](#); [Anderson and Lebiere \(1998\)](#); [Anderson et al. \(2004\)](#); [Anderson \(2007\)](#) among others. The main goal of this book is to take a hands-on approach to introducing ACT-R by constructing models that solve (or attempt to solve) linguistic problems. We will interleave theoretical notes and `pyactr` code throughout the book. We will therefore often display python code and its associated output in numbered examples and / or numbered blocks so that we can refer to specific parts of the code / output and link them to various components of the ACT-R theory

¹‘Control of thought’ is used here in a descriptive way, similar to the sense of ‘control’ in the notion of ‘control flow’ in imperative programming languages: it determines the order in which programming statements (or cognitive actions) are executed / evaluated, and thus captures essential properties of an algorithm and its specific implementation in a program (or cognitive system). ‘Control of thought’ is definitely not used in a prescriptive way roughly equivalent to ‘mind control’ / indoctrination.

or of the linguistic phenomenon or linguistic analysis we are modeling.

For example, when we want to discuss the code, we will display it as:

```
(1)  2 + 2 == 4      1
     3 + 2 == 6      2
```

Note the numbers on the far right – we can use them to refer to specific lines of code, e.g.: the equality in (1), line 1 is true, while the equality in (1), line 2 is false. We will sometime also include in-line Python code, displayed like this: `2 + 2 == 4`.

When we want to discuss both the code and its output, we will display the code and output in the same way they would appear in your interactive Python interpreter, for example:

```
[py1] >>> 2 + 2 == 4      1
      True                2
      >>> 3 + 2 == 6      3
      False               4
```

Once again, all lines are numbered (both the Python code and its output) so that we can refer back to it.

Examples – whether formulas, linguistic examples, examples of code etc. – are numbered as shown in (1) above. Blocks of python code meant to be run interactively, together with their associated output, are numbered separately as shown in [py1] above.

2.2 Why do we care about ACT-R, and cognitive architectures and modeling in general

Linguistics is part of the larger field of cognitive science. So the answer to the question “Why do we care about ACT-R and cognitive architectures / modeling in general?” is one that applies to cognitive sciences in general. Here is one recent formulation of what we take to be the right answer, taken from chapter 1 of [Lewandowsky and Farrell \(2010\)](#). That chapter mounts an argument for *process* models as the proper scientific target to aim for in the cognitive sciences – roughly, models of human language performance – rather than *characterization* models – roughly, models of human language competence. Both process and characterization models are better than simply *descriptive* models,

“whose sole purpose is to replace the intricacies of a full data set with a simpler representation in terms of the model’s parameters. Although those models themselves have no psychological content, they may well have compelling psychological implications. [Both characterization and process models] seek to illuminate the workings of the mind, rather than data, but do so to a greatly varying extent. Models that characterize processes identify and measure cognitive stages, but they are neutral with respect to the exact mechanics of those stages. [Process] models, by contrast, describe all cognitive processes in great detail and leave nothing within their scope unspecified. Other distinctions between models are possible and have been proposed [...], and we make no claim that our classification is better than other accounts. Unlike other accounts, however, our three classes of models map into three distinct tasks that confront cognitive scientists.

2.2. WHY DO WE CARE ABOUT ACT-R, AND COGNITIVE ARCHITECTURES AND MODELING IN GENERAL

Do we want to describe data? Do we want to identify and characterize broad stages of processing? Do we want to explain how exactly a set of postulated cognitive processes interact to produce the behavior of interest?" (Lewandowsky and Farrell, 2010, 25)

The advantages and disadvantages of process (performance) models relative to characterization (competence) models can be summarized as follows:

"Like characterization models, [the power of process models] rests on hypothetical cognitive constructs, but by providing a detailed explanation of those constructs, they are no longer neutral. [...] At first glance, one might wonder why not every model belongs to this class. After all, if one can specify a process, why not do that rather than just identify and characterize it? The answer is twofold. First, it is not always possible to specify a presumed process at the level of detail required for [a process] model [...] Second, there are cases in which a coarse characterization may be preferable to a detailed specification. For example, it is vastly more important for a weatherman to know whether it is raining or snowing, rather than being confronted with the exact details of the water molecules' Brownian motion. Likewise, in psychology [and linguistics!], modeling at this level has allowed theorists to identify common principles across seemingly disparate areas. That said, we believe that in most instances, cognitive scientists would ultimately prefer an explanatory process model over mere characterization." (Lewandowsky and Farrell, 2010, 19)

However, there is a more basic reason why generative linguists should consider process / performance models in addition to and at the same time as characterization / competence models. The reason is that *a priori*, we cannot know whether the best analysis of a linguistic phenomenon is exclusively a matter of competence or performance or both, in much the same way that we do not know in advance whether certain phenomena are best analyzed in syntactic terms or semantic terms or both.² Such determinations can only be done *a posteriori*: a variety of accounts need to be devised first spanning various points on the competence-performance spectrum, and they will have to be empirically and methodologically evaluated in specific ways as accounts of the specific phenomena they target.

Characterization / competence models have been the focus of linguistic theorizing over the 60 years in which the field of generative linguistics matured, and will rightly continue to be one of its main foci for the foreseeable future. We believe that the field of generative linguistics in general – and formal semantics in particular – is now mature enough to start considering process / performance models in a more systematic fashion.

Our main goal for this book is to enable semanticists to more productively engage with performance questions related to the linguistic phenomena they investigate. We do this by making it possible and relatively easy for semanticists, and generative linguists in general, to build integrated competence/performance linguistic models that formalize explicit (quantitative) connections between semantic theorizing and experimental data. Our book should

²We selected syntax and semantics only as a convenient example, since issues at the syntax/semantics interface are by now a staple of generative linguistics. Any other linguistic subdisciplines and their interfaces, e.g., phonology or pragmatics, would serve equally well to make the same point.

also be of interest to cognitive scientists in general interested to see more ways in which contemporary generative linguistic theorizing can contribute back to the broader field.

2.3 Knowledge in ACT-R

There are two types of knowledge in ACT-R: declarative knowledge and procedural knowledge (see also [Newell 1990](#)).

The declarative knowledge represents our knowledge of facts. For example, if one knows what the capital of the Netherlands is, this would be represented in one's declarative knowledge.

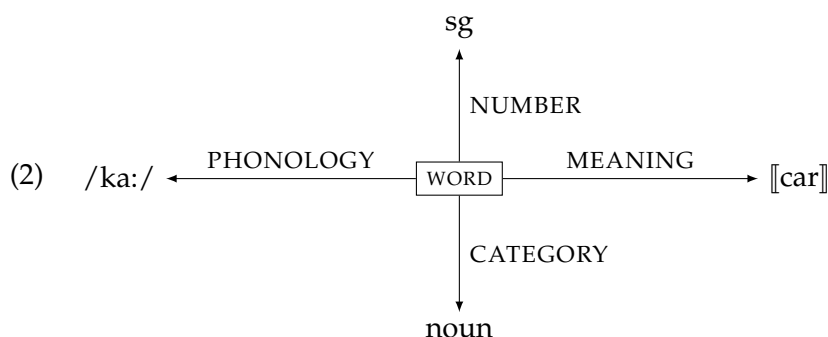

Procedural knowledge is knowledge that we display in our behavior (cf. [Newell 1973](#)). It is often the case that our procedural knowledge is internalized, we are aware that we have it but we would be hard pressed to explicitly and precisely describe it. Driving, swimming, riding a bicycle are examples of procedural knowledge. Almost all people who can drive / swim / ride a bicycle do so in an automatic way. They are able to do it but they might completely fail to describe how exactly they do it when asked. This distinction is closely related to the distinction between explicit ('know that') and implicit ('know how') knowledge in analytical philosophy (see [Ryle 1949](#) and [Polanyi 1967](#); see also [Davies 2001](#) and references therein for more recent discussions).

The two parts of knowledge in ACT-R are represented in two very different ways. The declarative knowledge is instantiated in chunks. The procedural knowledge is instantiated in production rules, or productions for short.

2.3.1 Representing declarative knowledge: chunks

Chunks are lists of attribute-value pairs, familiar to linguists from phrase structure grammars (e.g., LFG and HPSG). However, in ACT-R, we use the term *slot* instead of *attribute*. For example, we might think of one's knowledge of the word *car* as a chunk of type WORD with the value /ka:/ for the slot *phonology*, the value $\llbracket \text{car} \rrbracket$ for the slot *meaning*, the value noun for the slot *category* and the value sg for the slot *number*.

The slot values are the primitive elements /ka:/, $\llbracket \text{car} \rrbracket$, noun and sg, respectively. Chunks are boxed, whereas primitive elements are simple text. A simple arrow (\rightarrow) signifies that the chunk at the start of the arrow has the value at the end of the arrow in the slot with the name that labels the arrow.

The graph representation will be useful when we introduce activations and more generally, ACT-R subsymbolic components. The same chunk can be represented as an attribute-value matrix (AVM), and we'll overwhelmingly use AVM representations from now on.

$$(3) \quad \text{WORD} \begin{bmatrix} \text{PHONOLOGY:} & /ka:/ \\ \text{MEANING:} & \llbracket \text{car} \rrbracket \\ \text{CATEGORY:} & \text{noun} \\ \text{NUMBER:} & \text{sg} \end{bmatrix}$$

2.3.2 Representing procedural knowledge: productions

A production is an if-statement. It describes an action that takes place if the if-part is satisfied. For example, agreement on a verb can be (abstractly) expressed as follows: IF subject number in currently constructed sentence is sg THEN verb number in currently constructed sentence is sg. Of course, this is only half of the story – another rule would state: IF subject number in currently constructed sentence is pl THEN verb number in currently constructed sentence is pl. To repeat the basic intuition about the construction of these rules: productions specify conditions (the if-part of the statement); if these conditions are true, then actions take place (the THEN part of the statement).

Sticking with the example in the previous paragraph, it might look like a roundabout way of specifying agreement. Could we not state that the verb has the same number that the subject has? In fact, we can, if we use variables. Variables are assigned their value when they appear on the left side of a production. The variable keeps its value inside a rule (i.e., a rule is the scope for any variable assignment). Given that (and given the convention that variables are signaled in ACT-R using '='), we could write: IF subject number in currently constructed sentence is =x THEN verb number in currently constructed sentence is =x.

2.4 Using pyactr

After this brief introduction, we will continue by combining the theoretical part of ACT-R with discussing how it is implemented in `pyactr`. We will begin with describing details of declarative knowledge in ACT-R and its implementation in `pyactr`. After that we turn to the discussion of modules and buffers, which is needed before we can turn to the second type of knowledge in ACT-R, productions.

But as the very first thing, we have to import the relevant package:

```
[py2] >>> import pyactr as actr
```

1

We use the `as` keyword, so that every time we use the `pyactr` package, we can write `actr` instead of the longer `pyactr`.

2.5 Writing chunks in pyactr

There is one thing we have to do before writing chunks themselves: we should start by specifying a chunk type and all the slots you think it should have. This will help you be clear

about your intentions on what should be carried in declarative memory from the start. Let's create a chunk type that will correspond to our knowledge of words, as indicated above. Needless to say, we don't strive here for the linguistically realistic theory of word representations at this point. It is just a toy example, showing the inner workings of ACT-R. Anyway, here is our chunk type:

```
[py3] >>> actr.chunktype("word", "phonology, meaning, category, number")
```

1

The function `chunktype` creates a type `word`, which consists of the following slots: `phonology`, `meaning`, `category`, `number`. The type itself is written as the first argument of the function, the slots are written as the second argument and are separated by commas.

After declaring the chunk type, we can create new chunks using this type.

```
[py4] >>> car = actr.makechunk(nameofchunk="car", \
...                             typename="word", \
...                             phonology="/ka:/", \
...                             meaning="[[car]]", \
...                             category="noun", \
...                             number="sg")
>>> print(car)
word(category= noun, meaning= [[car]], number= sg, phonology= /ka:/)
```

1

2

3

4

5

6

7

8

The chunk is created using the function `makechunk`. Every `makechunk` has two fixed arguments: `nameofchunk` ([py4], line 1), `typename` ([py4], line 2). Furthermore, it has slot-value pairs, present in the chunk. Lines 3-6 show how values of slots are specified. You do not have to specify all the slots that a chunk of a particular type should have (in that case, the particular slots are empty). We finally print the chunk (line 7). Notice that the order of slot-value pairs is different than in instantiating the chunk (i.e., we defined `phonology` as first, but it appears as the last in the output). This is because chunks are unordered lists of slot-value pairs. Python assumes some arbitrary (alphabetic) ordering when printing chunks.

Specifying chunk types is optional. In fact, the information about chunk type is relevant for `pyactr`, but it has no theoretical significance (it's just a syntactic sugar). However, it is recommended, as doing so might clarify what kind of attribute-value matrices you will need in your model. Also if you don't specify the chunk type that your chunk uses, Python prints a warning message. This might help you debug your code (e.g., if you accidentally named your chunk "morpheme", you would get a warning message that a new chunk type has been created – probably, not what you wanted; warnings are not displayed in book). (See Python documentation for more on warnings.)

It is also recommended that you only use attributes you defined first (or you used in the first chunk of a particular type). However, you can always add new attributes along the way (it is assumed that other chunks up to now had no value for those attributes in that case). For example, imagine we realize that it's handy to specify what syntactic function a word is part of. We didn't have that in our example of `car`. So let's create a new chunk, `car2`, which is like `car` but it adds this extra piece of information (and we assume this word has been used as part of subject):

```
[py5] >>> car2 = actr.makechunk(nameofchunk="car2", \
...                             typename="word", \
```

1

2

```

...             phonology="/ka:/",\
...             meaning="[[car]]",\
...             category="noun",\
...             number="sg",\
...             syncat="subject")
>>> print(car2)
word(category= noun, meaning= [[car]], number= sg, phonology= /ka:/, syncat= subject)

```

Line 7 in [py5] is the new part. We are adding a new slot `syncat`, and assign it the value `subject`. The command goes through successfully (as shown by the fact that we can print `car2`), but a warning message is issued (not displayed above), namely “`UserWarning: Chunk type word is extended with new attributes.`”

There is another way of specifying a chunk, which is maybe more intuitive: using `chunkstring`. In that case, you write down the chunk type after the `isa`-attribute, and attribute value pairs are written after each other, separated only by a comma.

```

[py6] >>> car3 = actr.chunkstring(string="""
...     isa word
...     phonology '/ka:/'
...     meaning '[[car]]'
...     category 'noun'
...     number 'sg'
...     syncat 'subject'""")
>>> print(car3)
word(category= noun, meaning= [[car]], number= sg, phonology= /ka:/, syncat= subject)

```

We are using the new function `chunkstring`. It has the same power as `makechunk`. The argument `string` defines what the chunk consists of. The value pairs are written as a plain string. Notice that we use three quote marks, rather than one. These signal to Python that the string can appear on more than one line. The first slot-value pair ([py6], line 2) is special – it specifies the type of chunk, and a special slot is used for this, `isa`. Notice that the resulting chunk is identical to the previous one, as shown on [py6], line 8.

As we mentioned above, productions work by testing whether a particular condition is satisfied and then acting upon that. In practice, for most parts this means that productions check chunks. Thus, we have to define comparisons across chunks. This is done in an intuitive way: one chunk is identical to another if they have the same attributes and they have the same values for all the attributes. A chunk `a` is part of a chunk `b` if `a` has all the attributes of `b` and `a` has the same values as `b` in those attributes (however, chunk `b` might have extra attribute-value pairs).

`pyactr` overloads standard comparison operators for these tasks. The code below and its output should be self-explanatory:

```

[py7] >>> car2 == car2
True
>>> car == car2
False
>>> car <= car2
True
>>> car < car2

```

```

True
>>> car2 < car
False

```

Note that chunk types are irrelevant for deciding part-of relations. This might be counter-intuitive, but that's just how ACT-R works – chunk types are 'syntactic sugar' useful only for the human modeler. This means that if we define a new chunk type that happens to have the same slots as another chunk type, one might be part of the other:

```

[py8] >>> car2 == car2
True
>>> car == car2
False
>>> car <= car2
True
>>> car < car2
True
>>> car2 < car
False

```

2.6 Modules and buffers

Chunks do not live in a vacuum, they are always part of an ACT-R architecture, which consists of modules and buffers. Each module in ACT-R serves a different task. Furthermore, modules cannot be accessed or updated directly in ACT-R; rather, this always happens through the use of a buffer, and each module comes equipped with one such buffer. A buffer, in its turn, is a carrier of exactly one chunk.

In this chapter, we will be concerned with only two modules, the goal module (representing one's goals) and the declarative module (representing one's declarative knowledge). These are the two most common modules in ACT-R. They appear with their buffers, which are called goal and retrieval, respectively.

For the sake of concreteness, let's create the declarative module and the goal and retrieval buffers. And since it does not make sense to think about modules without instantiating a model in which these modules work, let's start by doing just that:

```

[py9] >>> actr.chunktype("synlabel", "category")
>>> noun = actr.makechunk(nameofchunk="noun",
...                       typename="synlabel",
...                       category="noun")
>>> noun < car2
True

```

The command above instantiated an ACTRModel as the value of the variable `retrieval`. We will now be filling in details of this model with information about buffers, models, and productions.

The ACT-R model comes equipped with basic modules we might need to use (e.g., the retrieval buffer, the goal buffer, the declarative memory). However, these buffers/modules are empty. Let's check that for the declarative memory. To simplify things, let's bind it to some short, easy to remember variables:

```
[py10] >>> agreement = actr.ACTRModel()
```

1

- `goal`, is an attribute in `ACTRModel` that carries the declarative memory. `dm` and `car2` carry the retrieval buffer and the goal buffer, respectively.

Let's check that `add` is empty:

```
[py11] >>> dm = agreement.decmem
```

1

We might want to add the best chunk we created so far – `dm`:

```
[py12] >>> dm
{}

```

1

2

- Chunks are added by the attribute `pyactr` on the declarative memory. As the argument, we specify a chunk (or chunks) that should be added.

`==>` now shows the chunk we added. It also ties the chunk to the time point at which it was introduced. Since we did not start any model simulation, the time point is 0 right now.

2.7 Writing productions in `=x`

In their core, productions are IF-statements.

Productions have two parts: left-hand side rules (tests) precede the double arrow (`=x`); right-hand side rules (actions) follow the arrow.

Let's now create productions that simulate a verb agreement.³ We will simplify things a lot. We will only care about 3rd person agreement, present tense. We will do no syntactic parsing, just assume that our memory includes only the subject of the clause and we have the verb of the clause at our disposal. Since our goal is creating verb agreement, we should assume that the verb itself is all the time in the goal. What should agreement do? One production should state that IF goal has a verb and task is to agree THEN the subject should be retrieved. The second production should state that IF subject number in retrieval is `productionstring` THEN verb number in goal is `name`. The third rule should say that if the verb is assigned a number the task is done.

Let's write down the second rule first.

```
[py13] >>> dm.add(car2)
>>> print(dm)
{word(category= noun, meaning= [[car]], number= sg, phonology= /ka:/, syncat= subject): {0.0}}
```

1

2

- Productions are created by the command `string` and they have two arguments (later on, we will see that there is a third argument): `==>` (the name of the production) and `==>` (the string that specifies what the production does).

³The full code for this model is also available as `u1_agreement` on <http://www.jakubdotlacil.com/tutorials> and in the appendix to this chapter.

- 2.–11. The left hand side of the rule and the right hand side of the rule are separated by `==>`. That is, what appears before `=` is tests, what appears after `>` are actions. Second, tests and actions have always the same structure: first, you specify what buffer should be considered: this is done by writing the name of the buffer between `chunkstring` and `isa` (see line 2 and 6). The name of the buffer has to match the name you used when you created these buffers. After choosing the buffer you specify a chunk (lines 3–5 and lines 7–10). In case of tests the chunks specified in a rule must be part of a chunk that is present in the corresponding buffer (i.e., the part-of test, discussed in Sect. writing-chunks-in-pyactr, must be true between the chunk specified in the test and the chunk in the corresponding buffer). Chunks in productions are written in the same way as chunks in the function `=retrieval>`: you write slot-value pairs, and each slot and value are separated by one or more spaces. (We also wrote each pair on a separate line, but that is just aesthetics.) The `?retrieval>` slot is used to specify chunk types.
- 12.–17. If all tests are true, then a chunk in a buffer is modified as specified after `==>`.

All in all, we can read the rule `agree` as follows: IF the goal buffer has a chunk with category `verb` and the task is to trigger `agreemnt` AND the retrieval buffer has a chunk with the category `noun` and `syncat` subject and it has some number, assigned to `x`, THEN modify the chunk in the goal buffer so that it carries the number that was assigned to `x`.

The other rule should appear as follows:

```
[py14] >>> agreement.productionstring(name="agree", string="""
...     =g>
...     isa verbagreement
...     task trigger_agreement
...     category 'verb'
...     =retrieval>
...     isa word
...     category 'noun'
...     syncat 'subject'
...     number =x
...     ==>
...     =g>
...     isa verbagreement
...     task done
...     category 'verb'
...     number =x
...     """)
{'=g': verbagreement(category= verb, task= trigger_agreement), '=retrieval': word(category= noun,
==>
{'=g': verbagreement(category= verb, number= =x, task= done)}}
```

6. Instead of `?retrieval>` in the test, we write `+retrieval>`. While `=retrieval>` tests whether the retrieval carries a particular chunk `+` queries the buffer directly. The query in this case checks whether the buffer is empty (i.e., it carries no chunk). Strictly speaking, this is not necessary (the model would work just as well without this test). But we add it here for instruction purposes.

13. We specify `dm` in actions. While `?` would modify a chunk present in the buffer, `=` states that a new chunk should be created/set. In case of the retrieval buffer chunks are 'created' by being retrieved from their module of declarative memory (in our case, `\textasciitilde{}g\textgreater{}{}`).

We will look at some more examples of querying in the next section (i.e., cases in which we use `PYACTR` instead of `add` in front of the name of a buffer). Before that, we add the third rule discussed above, which should check that the verb in goal carries a number, and if so, it should consider the task done.

```
[py15] >>> agreement.productionstring(name="retrieve", string=""""
...     =g>
...     isa verbagreement
...     task agree
...     category 'verb'
...     ?retrieval>
...     buffer empty
...     ==>
...     =g>
...     isa verbagreement
...     task trigger_agreement
...     category 'verb'
...     +retrieval>
...     isa word
...     category 'noun'
...     syncat 'subject'
...     """)
{'=g': verbagreement(category= verb, number= , task= agree), '?retrieval': {'buffer': 'empty'}}
==>
{'=g': verbagreement(category= verb, number= , task= trigger_agreement), '+retrieval': word(cate
```

8. `retrieve` is an action we did not see before. It discards the chunk present in the goal buffer.

2.8 More examples on queries

So far, we mentioned only one way of querying - checking that a buffer is full. Here are some more cases:

```
[py16] >>> agreement.productionstring(name="done", string=""""
...     =g>
...     isa verbagreement
...     task done
...     category 'verb'
...     number =x
...     ==>
...     ~g>""")
{'=g': verbagreement(category= verb, number= =x, task= done)}
==>
{'~g': None}
```

- This checks whether a buffer is full (whether it carries a chunk).
- This is true if the retrieval buffer is working on retrieving a chunk.
- This is true if the last retrieval failed (no chunk has been found).

2.9 Running a model

We have almost everything ready to run our first model, we are just missing one piece: having a chunk in the goal buffer in the start of our simulation (without that, there is no goal and without a goal, the model has no reason to change its internal state). So let's add the goal:

```
[py17] >>> '?g> buffer full' 1
        '?g> buffer full'      2
>>> '?retrieval> state busy'  3
        '?retrieval> state busy' 4
>>> '?retrieval> state error' 5
        '?retrieval> state error' 6
```

- The chunk is added to the goal buffer in the same way as to other modules and buffers – by the attribute `retrieve`.

We can now run the model.

```
[py18] >>> actr.chunktype("verbagreement", "task, category") 1
>>> agreement.goal.add(actr.chunkstring(string="isa verbagreement task agree category 'verb'")) 2
>>> agreement.goal 3
        {verbagreement(category= verb, task= agree)} 4
```

- First, we have to instantiate the simulation of the model.
- The simulation is run.

What you see in the output is the trace of a model. Each line specifies three elements: the first element is time (in seconds), the second element is the module that is affected, the third element is a description of what's happening to the module.

The first line states that conflict resolution takes place in the module procedural (i.e., the module responsible for controlling production rules). This happens at time 0. There is one rule that matches the current state of affairs, and that is `verb` (`agree` requires that the goal buffer has a chunk with the category `agree` and an empty and free retrieval buffer). It can fire (i.e., its left-hand side is satisfied by the state of the model at 0 ms, so we can proceed to the right-hand side of the production rule). In ACT-R, firing takes 50 ms, as we see above in the time specification of the third line. After that, goal is (vacuously) modified (the modification is vacuous given our rules above). Then the retrieval starts, and it takes 50 ms to finish the retrieval. When the retrieval happens (line 9), the retrieval buffer carries the right chunk. Followingly, a new rule can be selected, `done` (`pyactr` requires that the retrieval carries a subject chunk, and consequently, it modifies the chunk in goal to match the number between a verb and a noun).

After that, the last rule fires (parser), which clears the goal buffer. When the goal buffer is cleared, its information does not disappear. It is assumed in ACT-R that that information is transferred to the declarative memory. This is also the case here (our past goals become our newly acquired memory facts).

We can now check the final state of the declarative memory to see that this is the case:

```
[py19] >>> simulation = agreement.simulation()
>>> simulation.run()
(0, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0, 'PROCEDURAL', 'RULE SELECTED: retrieve')
(0.05, 'PROCEDURAL', 'RULE FIRED: retrieve')
(0.05, 'g', 'MODIFIED')
(0.05, 'retrieval', 'START RETRIEVAL')
(0.05, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0.05, 'PROCEDURAL', 'NO RULE FOUND')
(0.1, 'retrieval', 'CLEARED')
(0.1, 'retrieval', 'RETRIEVED: word(category= noun, meaning= [[car]], number= sg, phonology= /ka/
(0.1, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0.1, 'PROCEDURAL', 'RULE SELECTED: agree')
(0.15, 'PROCEDURAL', 'RULE FIRED: agree')
(0.15, 'g', 'MODIFIED')
(0.15, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0.15, 'PROCEDURAL', 'RULE SELECTED: done')
(0.2, 'PROCEDURAL', 'RULE FIRED: done')
(0.2, 'g', 'CLEARED')
(0.2, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0.2, 'PROCEDURAL', 'NO RULE FOUND')
```

2.10 Example 2 – a top-down parser

We will now turn to a more realistic case, a parser. There will be more parsers considered throughout the tutorials. Our starting point is one of the simplest parsers – a top-down parser.⁴

Suppose we have a context-free grammar with the following rules:

```
S    → NP VP
NP   → ProperN
VP   → V NP
```

Furthermore, there are two nouns and one verb in our language: Mary, Bill, likes. We will analyze one sentence with our parser, Mary likes Bill.

A top-down parser can be understood as a push-down automaton. Push-down automata have a memory, represented as a stack. In the parser, the stack represents categories that have to be parsed. For example, the stack may consist of one symbol, S - this would express that a sentence needs to be parsed (obviously, this is the starting point of a parser). Or the stack could consist of two elements: NP, VP – expressing that the parser needs to parse an NP, followed by parsing a VP.

⁴The full code for this model is also available as `u1_topdownparser` on: <http://www.jakubdotlacil.com/tutorials>

The parser proceeds by modifying the contents of its stack based on two pieces of information: the top element on its stack (also written as the leftmost element below) and, possibly, a word that has to be parsed (the leftmost word in the stream of words).

We can sum up the parsing rules into just two general algorithm schemata (see, for example, [Hale 2014](#)):

- **expand**: if the stack shows a symbol X on top, and the grammar contains a rule $X \rightarrow A$ or $X \rightarrow A, B$ or the symbol A, B or the symbol A , respectively.
- **scan**: if the stack shows a terminal and w , the word to be parsed, is of the right category, then remove the terminal from the stack and w from the parsed sentence.

We will now implement these general parsing rules to our grammar, which will be able to parse the sentence Mary likes Bill.

2.10.1 First steps in the model

Let us start with the first standard step, importing `dm`.

```
[py20] >>> dm
          {verbagreement(category= verb, number= sg, task= done): {0.2}, word(category= noun, meaning= [[c
```

Now, we should specify what chunktypes we need. We will have one chunktype for the parser. This will keep the information about stack contents, what word was parsed but also what the current task of the parser is (for most parts, it will be just that, parsing).

```
[py21] >>> import pyactr as actr
```

- The chunk type has four slots: what task we are doing, what the current top element in the stack is, what the bottom element is and what the parsed word is. Note that we have only two positions in our chunktype, stack top and stack bottom. This suffices for the simple case of binary structures we consider here, so we will leave it at this.

The second chunktype will represent the sentence. This might look weird: why should we represent a sentence in a chunk? In most of the cases, the sentence is external to an agent, it's what the agent reads or hears. However, at this point we have no way to represent the surrounding environment, so we have to represent a sentence internally, as a chunk. Later on, we will see a more elegant solution. The chunktype sentence will be assumed to carry at most three words.

```
[py22] >>> actr.chunktype("parsing", "task stack_top stack_bottom parsed_word ")
```

We will now initialize the model.

```
[py23] >>> actr.chunktype("sentence", "word1 word2 word3")
```

- We call our model `parsing`.
- We bind the declarative memory to the variable `sentence`. This step is not necessary, but helpful if we want to expect the memory later. The same is true for the goal buffer.

The goal buffer will carry the information about parsing (that is, it will have the chunk "g2", whose type was already created). But we also need to carry the information about the parsed sentence (the chunk `delay`). It would be nice to leave that information to the environment but we cannot do it yet, so let's create a second buffer, which is identical to goal and which carries the information about a sentence. In fact, that is not such a strange solution. ACT-R commonly assumes two goal buffers, one, which we used so far and which keeps information about one's goals, another one which keeps the internal image of current information. It might not be so far-fetched to use the imaginal buffer for the sentence itself. We will start this new buffer.

```
[py24] >>> parser = actr.ACTRModel() 1
>>> dm = parser.decmem 2
>>> g = parser.goal 3
```

- The first line creates a new goal buffer, imaginal buffer. The string `retrieve` sets the name under which the model will recognize the buffer (e.g., in production rules). In the second line, we also specify the `retrieving` attribute of the imaginal buffer. This attribute encodes the delay required to set a chunk in the buffer. That is, it would take 0.2 s to set a chunk in g2. This is the standard value for the imaginal buffer (the goal buffer sets a chunk immediately).

We can now add chunks into g and g2. We need to set two values in two goal buffers. One way to do this is to specify the values in the

```
[py25] >>> parser.goal = "g2" 1
>>> parser.goal.delay = 0.2 2
>>> g2 = parser.goal 3
```

- We assume that the parser's goal is to parse a sentence.
- The sentence to be parsed is *Mary likes Bill*.

The toughest part is coming now: how to code the parsing itself?

We will assume that grammar (and parsing rules stemming from grammar) is part of production knowledge. This is in contrast to lexical information, which is commonly treated as part of declarative memory (see [Lewis and Vasishth 2005](#), for arguments for this distinction). So, our first task is to specify lexical knowledge. Let's do that (only syntactic categories will be specified):

```
[py26] >>> g.add(actr.chunkstring(string="isa parsing task parse stack_top 'S'")) 1
>>> g2.add(actr.chunkstring(string="isa sentence word1 'Mary' word2 'likes' word3 'Bill'"))
```

- We start by creating a new type that will accommodate lexical information.

2.–4. We have three words. Their values should be obvious.

We now have to specify production rules that mimic context-free grammar rules and that encode top-down parsing, represented in the schemata `expand` and `scan`.

2.10.2 Production rules

Let's start with the first rule, expanding S into NP and VP. This should be relatively straightforward. We specify it as:

```
[py27] >>> actr.chunktype("word", "form, cat") 1
>>> dm.add(actr.chunkstring(string="isa word form 'Mary' cat 'ProperN'")) 2
>>> dm.add(actr.chunkstring(string="isa word form 'Bill' cat 'ProperN'")) 3
>>> dm.add(actr.chunkstring(string="isa word form 'likes' cat 'V'")) 4
```

2. The rule tests against the goal buffer.
- 3.-5. It requires that the goal buffer carries a chunk whose task is to parse and whose element on top is S.
7. Its action is to modify the goal buffer.
- 8.-10. The rule will set the top element as NP and the bottom as VP. That is, this is the rule that expands S into NP and VP according to the abstract schema discussed above (see the general algorithm schema expand).

Notice that this oversimplifies things slightly. If we now have a symbol following S in the stack, it would be overwritten by VP - hardly a behavior we would want to have. This oversimplification is to a large extent caused by the fact that we only work with two-element stack. It will not affect our example or several other examples, so we will leave this simplification in place.

The second rule states that NP is expanded into ProperN:

```
[py28] >>> parser.productionstring(name="expand: S->NP VP", string=""" 1
...     =g> 2
...     isa parsing 3
...     task parse 4
...     stack_top 'S' 5
...     ==> 6
...     =g> 7
...     isa parsing 8
...     stack_top 'NP' 9
...     stack_bottom 'VP' 10
... """) 11
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= S, task= parse)} 12
==> 13
{'=g': parsing(parsed_word= , stack_bottom= VP, stack_top= NP, task= )} 14
```

9. The rule says that the symbol on the top of the stack should be rewritten from NP to N. Notice that unlike the previous rule, nothing is done to the bottom of the stack. Thus, it will be left unmodified.

The third rule in our grammar describes the expansion of VP into V and NP. So let's deal with it in the parallel way as the previous rules:

```
[py29] >>> parser.productionstring(name="expand: NP->ProperN", string="""
...     =g>
...     isa parsing
...     task parse
...     stack_top 'NP'
...     ==>
...     =g>
...     isa parsing
...     stack_top 'ProperN'
... """)
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= NP, task= parse)}
==>
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= ProperN, task= )}
```

1.-10. Notice that the rule is almost identical to the first rule. We only changed the symbols, according to the context-free grammar rules.

Now, for the most complex part. Once we have terminals (ProperN, V), we have to check that the terminal matches the category of the word to be parsed. If so, the word is scanned.

We achieve this by splitting the task into two rules. If we have a terminal, say ProperN, the category of the word has to be retrieved from memory (rule `print`). If the category matches the top of stack, the word is scanned.

```
[py30] >>> parser.productionstring(name="expand: VP -> V NP", string="""
...     =g>
...     isa parsing
...     task parse
...     stack_top 'VP'
...     ==>
...     =g>
...     isa parsing
...     stack_top 'V'
...     stack_bottom 'NP'
... """)
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= VP, task= parse)}
==>
{'=g': parsing(parsed_word= , stack_bottom= NP, stack_top= V, task= )}
```

2.-5. We test that the top of the stack has a terminal, ProperN.

6.-8. The imaginal buffer has the leftmost word; the word is assigned to the variable w1.

10.-12. The goal is switched from parsing to retrieving.

13.-15. The retrieval starts. We are retrieving the chunk with the form of w1. This will retrieve a chunk with the lexical information about the particular word.

```
[py31] >>> parser.productionstring(name="retrieve: ProperN", string="""
...     =g>
...     isa parsing
...     task parse
... """)
```

```

...     stack_top 'ProperN'                                5
...     =g2>                                                6
...     isa sentence                                         7
...     word1 =w1                                            8
...     ==>                                                  9
...     =g>                                                 10
...     isa parsing                                          11
...     task retrieving                                     12
...     +retrieval>                                         13
...     isa word                                             14
...     form =w1                                            15
...     """)                                               16
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= ProperN, task= parse), '=g2': sentence(word1=
==>                                                         18
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= , task= retrieving), '+retrieval': word

```

5. We test that the top of the stack has a terminal, V. APart from this one line, the rule is identical to the previous one.

Now, we define the rule that deals with the retrieved information and scans the upcoming word:

```

[py32] >>> parser.productionstring(name="retrieve: V", string="" 1
...     =g>                                                2
...     isa parsing                                         3
...     task parse                                          4
...     stack_top 'V'                                       5
...     =g2>                                                6
...     isa sentence                                         7
...     word1 =w1                                            8
...     ==>                                                  9
...     =g>                                                 10
...     isa parsing                                          11
...     task retrieving                                     12
...     +retrieval>                                         13
...     isa word                                             14
...     form =w1                                            15
...     """)                                               16
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= V, task= parse), '=g2': sentence(word1=
==>                                                         18
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= , task= retrieving), '+retrieval': word

```

- 2.-6. This checks that the goal buffer has the task word1. Furthermore, it assigns stack symbols to two variables.
- 7.-10. The syntactic category of the retrieval must match the symbol on top of the stack.
- 11.-15. The imaginal buffer carries the sentence. Three words are assigned to three variables.
- 17.-22. This action achieves that the symbol on the bottom of the stack is moved to the top position. Notice also that the goal buffer has been changed into a new stage, print.

This is not necessary, it serves only the purpose of checking that everything went fine. We want to print the word that has been currently parsed. We will do that in a separate production. For the same reason, we keep the information about the currently parsed word in the goal buffer, in the slot `parsed_word`.

- 23.–27. Words are moved one level up (the word on the second position is moved to the first position etc.). The last position is left empty.

The printing production that follows scanning the string, is specified below:

```
[py33] >>> parser.productionstring(name="scan: string", string="""
...     =g>
...     isa parsing
...     task retrieving
...     stack_top =y
...     stack_bottom =x
...     =retrieval>
...     isa word
...     form =w1
...     cat =y
...     =g2>
...     isa sentence
...     word1 =w1
...     word2 =w2
...     word3 =w3
...     ==>
...     =g>
...     isa parsing
...     task print
...     stack_top =x
...     stack_bottom empty
...     parsed_word =w1
...     =g2>
...     isa sentence
...     word1 =w2
...     word2 =w3
...     word3 empty
...     """)
{'=g': parsing(parsed_word= , stack_bottom= =x, stack_top= =y, task= retrieving), 29='retrieval':
==>
{'=g': parsing(parsed_word= =w1, stack_bottom= empty, stack_top= =x, task= print), 31='g2': senten
```

- 2.–4. This tests that the goal buffer has the task show.

- 5.–7. The value of the slot `parsed_word` in the imaginal buffer is not empty (the squiggle is negation).

- 9.–10. -

- 11.–12. This part will print the parsed word. `!g>` says that Python should carry out an action in the goal buffer. After `!g>`, we have to specify what Python should do: we specify that

we want Python to show something (i.e., it should execute the method `parsed_word`) and what should be shown, that is, the value of the slot `word1`.

13.–16. The last action deletes whatever was in `print`.

The last production we have to consider is the production at the end of parsing. The parsing ends when productions has the value empty and the task is `g` (i.e., no parsing or retrieving is going on in the goal buffer). As a way of summary, we will also print all our rules.

```
[py34] >>> parser.productionstring(name="print parsed word", string="""
...     =g>
...     isa parsing
...     task print
...     =g2>
...     isa sentence
...     word1 ~empty
...     ==>
...     !g>
...     show parsed_word
...     =g>
...     isa parsing
...     task parse
...     parsed_word None""")
{'=g': parsing(parsed_word= , stack_bottom= , stack_top= , task= print), '=g2': sentence(word1=
==>
{'!g': ([ 'show', 'parsed_word'], {}), '=g': parsing(parsed_word= None, stack_bottom= , stack_top=
```

1. We bind the output to the variable `g2`. The output is all the production rules in the model. We can print them afterwards.

6.–8. We check that there is no leftmost word (the whole sentence was parsed).

14.–15. The imaginal and goal buffers are cleared.

16. We print all production rules.

2.10.3 Running the model

We run the model in the same way as before.

```
[py35] >>> productions = parser.productionstring(name="done", string="""
...     =g>
...     isa parsing
...     task print
...     =g2>
...     isa sentence
...     word1 empty
...     ==>
...     =g>
...     isa parsing
...     task done
```

```

...      !g>                                     12
...      show parsed_word                         13
...      ~g2>                                    14

{'=g': parsing(parsed_word= , stack_bottom= , stack_top= , task= done), '~g2': None, '~g': None,

```

- We instantiate the simulation of the model.
- The simulation is run.

This all looks good. We parsed the three words and we ended up in the stage done. We can also check our declarative memory. Since we cleared g and g2 at the end of done, it should consist of those elements (it should also carry the chunks we put in there before, the lexical knowledge). The chunks from stack_top and stack_bottom should have empty positions in word1 and word3, as well as parsed_word – steps. Let's see.

```

[py36] >>> sim = parser.simulation()              1
>>> sim.run()                                     2

(0.75, 'g2', 'MODIFIED')	72
(0.75, 'PROCEDURAL', 'CONFLICT RESOLUTION')	73
(0.75, 'PROCEDURAL', 'RULE SELECTED: done')	74
(0.8, 'PROCEDURAL', 'RULE FIRED: done')	75
Bill	76
(0.8, 'g', 'EXECUTED')	77
(0.8, 'g', 'MODIFIED')	78
(0.8, 'g2', 'CLEARED')	79
(0.8, 'g', 'CLEARED')	80
(0.8, 'PROCEDURAL', 'CONFLICT RESOLUTION')	81
(0.8, 'PROCEDURAL', 'NO RULE FOUND')	82

This is all good.

As a further check, let's see whether our simple parser correctly fails if we feed it an ungrammatical sentence, say *Bill Mary likes*. It should fail during parsing of the second word, *Mary*, because the noun would not match its expectations.

We add relevant chunks into the goal and the imaginal buffers and start the new simulation.

```
[py37] >>> dm
          {parsing(parsed_word= Bill, stack_bottom= empty, stack_top= empty, task= done): {0.8}, word(cat=
```

- The goal should be to parse a sentence, as before.
- The imaginal buffer should carry the information about the sentence, *Bill Mary likes*.

This is good. The parser correctly parsed the first word, but it failed at the second word. After it was retrieved, the parser could not match its category to the top of the stack (which required V).

But it is not enough that the parser correctly parses grammatical sentences and fails in ungrammatical ones. ACT-R is not a theory of computationally effective parsers, it is a theory of human cognition. ACT-R parsers should then model human processing as realistically as possible. Is that so in this case? One thing we would expect from such a parser is that its time requirements should correspond to human processing. We see that it takes 800 ms to parse the sentence *Mary likes Bill*. This might be roughly correct, but there are things to worry about. For example, the parser requires this much time while abstracting away from what people have to do during parsing (internalizing visual information, projecting sentence meaning, a.o.), so ultimately, 800 ms might be too much given the amount of work this parser does. Another worry is that retrieving lexical information always takes 50 ms (see above). But this is hardly realistic. We know that lexical retrieval is dependent on various factors, and frequency is probably the most relevant one. This is completely ignored here. Finally, top-down parsers works quite well for a right-branching structures like the sentence *Mary likes Bill*, but it would have problems with left branching. In left branching the parser would have to store as many symbols on the stack as there are levels of embedding. Since every expansion of a rule takes 50 ms, we would expect that left branching structures of n -level embeddings should take $50 * n$ ms. This is at odds with human performance (cf. [Resnik 1992](#)). Thus, there is a lot of room for improvement to get to a more plausible human parser.

2.10.4 Stepping through a model

So far, when we checked a model, we always did that in one step, by running it from start to the end. This is fine, but there are cases when we might want to proceed more carefully. For example, we might want to check each step to see at which point the goal buffer gets its `pyactr`. Or our model is running an infinite loop, and we only want to check what's going on in the first few rules. Or we want to check what our declarative memory looks like after the retrieval is cleared for the first time. Etc.

For all these cases, it is handy to step through the simulation, rather than running it as a whole. Let's start our model again and do that.

```
[py38] >>> g.add(actr.chunkstring(string="isa parsing task parse stack_top 'S'")) 1
>>> g2.add(actr.chunkstring(string="isa sentence word1 'Bill' word2 'Mary' word3 'likes'")) 2
>>> sim = parser.simulation() 3
>>> sim.run() 4
(0, 'PROCEDURAL', 'CONFLICT RESOLUTION') 5
(0, 'PROCEDURAL', 'RULE SELECTED: expand: S->NP VP') 6
(0.05, 'PROCEDURAL', 'RULE FIRED: expand: S->NP VP') 7
(0.05, 'g', 'MODIFIED') 8
(0.05, 'PROCEDURAL', 'CONFLICT RESOLUTION') 9
(0.05, 'PROCEDURAL', 'RULE SELECTED: expand: NP->ProperN') 10
(0.1, 'PROCEDURAL', 'RULE FIRED: expand: NP->ProperN') 11
(0.1, 'g', 'MODIFIED') 12
(0.1, 'PROCEDURAL', 'CONFLICT RESOLUTION') 13
(0.1, 'PROCEDURAL', 'RULE SELECTED: retrieve: ProperN') 14
(0.15, 'PROCEDURAL', 'RULE FIRED: retrieve: ProperN') 15
(0.15, 'g', 'MODIFIED') 16
(0.15, 'retrieval', 'START RETRIEVAL') 17
(0.15, 'PROCEDURAL', 'CONFLICT RESOLUTION') 18
(0.15, 'PROCEDURAL', 'RULE SELECTED: scan: string') 19
(0.2, 'retrieval', 'CLEARED') 20
(0.2, 'PROCEDURAL', 'RULE FIRED: scan: string') 21
(0.2, 'retrieval', 'RETRIEVED: word(cat= ProperN, form= Bill)') 22
(0.2, 'g', 'MODIFIED') 23
(0.2, 'g2', 'MODIFIED') 24
(0.2, 'PROCEDURAL', 'CONFLICT RESOLUTION') 25
(0.2, 'PROCEDURAL', 'RULE SELECTED: print parsed word') 26
(0.25, 'PROCEDURAL', 'RULE FIRED: print parsed word') 27
Bill 28
(0.25, 'g', 'EXECUTED') 29
(0.25, 'g', 'MODIFIED') 30
(0.25, 'PROCEDURAL', 'CONFLICT RESOLUTION') 31
(0.25, 'PROCEDURAL', 'RULE SELECTED: expand: VP -> V NP') 32
(0.3, 'PROCEDURAL', 'RULE FIRED: expand: VP -> V NP') 33
(0.3, 'g', 'MODIFIED') 34
(0.3, 'PROCEDURAL', 'CONFLICT RESOLUTION') 35
(0.3, 'PROCEDURAL', 'RULE SELECTED: retrieve: V') 36
(0.35, 'PROCEDURAL', 'RULE FIRED: retrieve: V') 37
(0.35, 'g', 'MODIFIED') 38
(0.35, 'retrieval', 'START RETRIEVAL') 39
(0.35, 'PROCEDURAL', 'CONFLICT RESOLUTION') 40
(0.35, 'PROCEDURAL', 'NO RULE FOUND') 41
(0.4, 'retrieval', 'CLEARED') 42
(0.4, 'retrieval', 'RETRIEVED: word(cat= ProperN, form= Mary)') 43
(0.4, 'PROCEDURAL', 'CONFLICT RESOLUTION') 44
(0.4, 'PROCEDURAL', 'NO RULE FOUND') 45
```

Ok, what's that? Little happened so far. The simulation only proceeded through the first step. Let's add some more steps:

```
[py39] >>> g.add(actr.chunkstring(string="isa parsing task parse stack_top 'S'")) 1
>>> g2.add(actr.chunkstring(string="isa sentence word1 'Bill' word2 'likes' word3 'Mary'")) 2
>>> sim = parser.simulation() 3
```

```
>>> sim.step() 4
(0, 'PROCEDURAL', 'CONFLICT RESOLUTION') 5
```

- We use the method `Environment`, with the parameter number of steps (in this case, 10 steps).

Let's now move to the point at which the rule 'scan: string' has fired.

In order to be able to do that, we have to be able to see into the current event. The current event is an attribute of the simulation. This is how we can check it:

```
[py40] >>> sim.steps(10) 1
(0, 'PROCEDURAL', 'RULE SELECTED: expand: S->NP VP') 2
(0.05, 'PROCEDURAL', 'RULE FIRED: expand: S->NP VP') 3
(0.05, 'g', 'MODIFIED') 4
(0.05, 'PROCEDURAL', 'CONFLICT RESOLUTION') 5
(0.05, 'PROCEDURAL', 'RULE SELECTED: expand: NP->ProperN') 6
(0.1, 'PROCEDURAL', 'RULE FIRED: expand: NP->ProperN') 7
(0.1, 'g', 'MODIFIED') 8
(0.1, 'PROCEDURAL', 'CONFLICT RESOLUTION') 9
(0.1, 'PROCEDURAL', 'RULE SELECTED: retrieve: ProperN') 10
(0.15, 'PROCEDURAL', 'RULE FIRED: retrieve: ProperN') 11
```

The event has three arguments: time, proc and action. Time is the time at which the event took place. proc is the name of the module that's affected. action represents the action that's taking place. So, let's move to the action of firing of 'scan: string'.

```
[py41] >>> sim.current_event 1
Event(time=0.15, proc='PROCEDURAL', action='RULE FIRED: retrieve: ProperN') 2
```

- 1 We specify a loop that will run until the action is 'scan: string'.
- 2 The simulation proceeds forward while the loop is True.

Now, we can check, for example, what our buffers look like:

```
[py42] >>> while sim.current_event.action != 'RULE FIRED: scan: string': 1
...     sim.step() 2
... 3
(0.15, 'g', 'MODIFIED') 4
(0.15, 'retrieval', 'START RETRIEVAL') 5
(0.15, 'PROCEDURAL', 'CONFLICT RESOLUTION') 6
(0.15, 'PROCEDURAL', 'NO RULE FOUND') 7
(0.2, 'retrieval', 'CLEARED') 8
(0.2, 'retrieval', 'RETRIEVED: word(cat= ProperN, form= Bill)') 9
(0.2, 'PROCEDURAL', 'CONFLICT RESOLUTION') 10
(0.2, 'PROCEDURAL', 'RULE SELECTED: scan: string') 11
(0.25, 'PROCEDURAL', 'RULE FIRED: scan: string') 12
```

2.11 Exercise

As an exercise, consider expanding the top-down parser. Additionally to what we have now, we should also be able to process the following rules from our grammar:

VP \rightarrow V CP

VP \rightarrow V

CP \rightarrow C S

Furthermore, we will add following lexical items into our memory: that, cat C; believes, cat V; sleeps, cat V; John, cat ProperN.

With these additions, you should be able to parse sentences like ‘Mary believes that Bill sleeps’ (but see below).

You can probably see right away that the created parser might run into problems. For example, the parser might get stuck if you feed it the sentence ‘Mary believes that Bill likes Mary’ and it decides to expand the first VP into V and NP or into just V. This is a typical property of top-down parsers: they hypothesize about categories/structures before seeing them. In our model, the parser will have several ways to expand VP, so it should run into troubles when it uses the rule that happens to be incompatible with input.

So, what happens in those cases? What will our ACT-R top down parser do? What do you think?

The problem with top-down parsing can be avoided if we switch our strategy: rather than postulating the structure before having evidence, we might want to defer creating the structure until all the relevant evidence is available. This different strategy has a name - it is a bottom-up parser. We will consider how it can be built in ACT-R in the next chapter, as well as some other models relevant for language.

2.12 The environment in ACT-R

2.12.1 Introduction

We introduced a few modules of ACT-R in the previous chapter:

- the declarative memory module and its retrieval buffer
- the goal buffer
- the imaginal buffer
- procedural knowledge

These are core modules of ACT-R. But using just those modules yields a model that is completely internal. It does not interact in any way with the environment. We are going to change that in this chapter.

2.12.2 A simple lexical decision task

We will consider a very simple lexical decision task, one in which the ACT-R model searches a (virtual) screen, finds a word, and if the word matches its (extremely impoverished) lexicon, it will press the J key, otherwise it will press the F key.

We start by import `focus_position`.

```
[py1] >>> g
        {parsing(parsed_word= Bill, stack_bottom= empty, stack_top= VP, task= print)}
        >>> g2
        {sentence(word1= Bill, word2= likes, word3= Mary)}
```

Creating an environment

ACT-R models can interact with an environment, which, currently, is just a (simulated) computer screen, and a very primitive one at that (currently, only plain text is supported). We start it as follows:

```
[py43] >>> import pyactr as actr
```

The class `simulated_screen_size` has various arguments when initialized. Here we only specified `viewing_distance` (this indicates at which position the eye focus is when the simulation starts). Two other most relevant arguments are `automatic_visual_search` and `False`. The first argument specifies the size of the screen we are trying to simulate in our model. If you are running a simulation of an experiment, you would encode the physical size of the screen (in cm) of the monitor you used. The second important argument specifies the distance from which the monitor is seen. Some reasonable defaults are assumed here: the screen is of size 50x28 cm, the distance is 50cm.

After the environment is initialized, we can initialize our ACT-R model.

```
[py44] >>> environment = actr.Environment(focus_position=(0,0))
```

The initialization is similar as in the previous chapter, the only difference is that this time, we specify arguments when creating the model. First of all, we state what environment the model is interacting with. This is the environment we just created. Second, we specify a parameter in the model. The parameter is `MODEL_PARAMETERS` and we set it to `for`. This will ensure that ACT-R does not search the environment unless we specifically tell it to do so (more on this later).

There are many other parameters in the model, and a big part of these tutorials is to discuss their role in cognitive modelling. You can glance at all possible parameters available by checking the attribute `visual_location`:

```
[py45] >>> model = actr.ACTRModel(environment=environment, automatic_visual_search=False)
```

Adding standard modules

After this, we add modules we used in the last chapter. Since we are simulating a primitive lexical decision task, we will need some words in the declarative memory that ACT-R can access and check against the stimuli in the simulated experiment. So, we add a few words into the declarative memory.

```
[py46] >>> model.MODEL_PARAMETERS
        {'latency_factor': 0.1, 'eye_mvt_angle_parameter': 1, 'utility_alpha': 0.2, 'activation_trace':
```

4–6 Notice that we add three words into our declarative memory using a `visual` loop, rather than tediously writing the code for each word. This way of adding chunks can save a lot of time if you want to add a lot of elements (e.g., the whole lexicon).

Finally, we add a chunk into the goal buffer that will be present there when our simulation starts.

```
[py47] >>> actr.chunktype("goal", "state") 1
>>> actr.chunktype("word", "form") 2
>>> dm = model.decmem 3
>>> for i in {"elephant", "dog", "crocodile"}: 4
...     dm.add(actr.makechunk(typename="word", form=i)) 5
... 6
>>> g = model.goal 7
```

Visual module

The visual module will allow the ACT-R model to ‘see’ the environment. This is achieved through the interaction of two buffers: `visual_location` searches the environment for elements matching its search criteria; `color` stores the element that was found using `screen_x`. The two buffers are sometimes called the visual Where and What buffers.

The visual Where buffer checks the environment (the screen) and outputs the location of an element on the screen that matches search criteria. Three slots are possible for a search: `screen_y`, `screen_x 100` `screen_y 100` (the horizontal position on the screen) and `screen_x <100` (the vertical position on the screen). The `x` and `y` positions can be specified in precise terms (e.g., find an element in the location `screen_x >100` where numbers represent pixels) or only roughly. Stating `screen_x lowest` would search the part of the screen that has 100 or fewer pixels on the `x`-axis and `screen_x highest` would search the other part of the screen. Three other keywords are supported in search. `screen_x closest` expresses that the element with the lowest position on the horizontal axis should be found. `pyactr` searches for the element with the highest position on the same axis. `press_key` searches for the closest element (the axis is ignored in this case). The same keywords and search terms can be used for the `y` axis.

The visual What buffer stuffs the element whose location was found in the Where buffer. Thus, usually, this buffer follows the workings of the previous buffer, as we’ll see in production rules.

The vision module as a whole is an implementation of an EMMA (Eye Movements and Movement of Attention) computational model (Salvucci, 2001), which, in turn, is a generalization (and simplification) of E-Z Reader model (Reichle et al., 1998). While the latter model is used for reading, the EMMA model attempts to simulate any visual task, not just reading. Empirical support and modelling claims for E-Z Reader and EMMA can be found in (Reichle et al., 1998; Salvucci, 2001; Staub, 2011). Since these issues go beyond the scope of the book, we will not discuss them here.

2.12.3 Motor module

The motor module models pressing a key on a keyboard (or typing, if more key strokes are chained). The ACT-R typing model is based on EPIC’s Manual Motor Processor (Meyer and

Kieras, 1997). It has one buffer that accepts requests to execute motor commands. The ACT-R model implemented in start is more limited, it currently supports only one command can be: that of `attend_probe`). But this should suffice for simulations of many experimental designs, since it is common to allow only for keyboard interaction in experiments.

The hands of the model are assumed to be positioned on the standard keyboard at the home row position (index fingers are at F and J). The model assumes a competent but not an expert typist.

Adding productions

In the production, we want to model a lexical decision task. Five rules will suffice for this.

The first rule will ensure that the visual Where buffer looks for a word in the (virtual) screen.

```
[py48] >>> g.add(actr.makechunk(nameofchunk='start', typename="goal", state='start')) 1
```

The rule requires that the `move_attention` chunk is in the goal buffer (lines 2 – 4) and there is no chunk in the visual location buffer (lines 5 – 6). If this is satisfied, the goal will be updated (lines 8 – 10) and the visual location will be updated (lines 11 – 13). The visual location is updated with the position of the closest element (line 13).

After this rule fired, the ACT-R model would know a position of an element but it would not know what that element is. For that, the visual What buffer has to be employed. This is done in the second rule, `screen_pos`.

```
[py49] >>> model.productionstring(name="find_word", string=""" 1
...     =g> 2
...     isa    goal 3
...     state  'start' 4
...     ?visual_location> 5
...     buffer empty 6
...     ==> 7
...     =g> 8
...     isa    goal 9
...     state  'attend' 10
...     +visual_location> 11
...     isa _visuallocation 12
...     screen_x closest""") 13
{'?visual_location': {'buffer': 'empty'}, '=g': goal(state= start)} 14
==> 15
{'=g': goal(state= attend), '+visual_location': _visuallocation(color= , screen_x=6closest, scre
```

This rule checks that there is an element in the visual Where buffer (lines 5 and 6). If so and if the visual What buffer is free (i.e., it does not carry out any action, a new chunk is added to it (lines 13 – 16). The last line states that the visual location is cleared.

Notice how the visual buffer finds an element. This is achieved by specifying the command in the chunk as `_manual`. This requires that the attention is moved to a new position. The new position is specified in the slot `cmd`, and it is the position that the visual location has uncovered.

The interaction between the two buffers in vision simulates a two-step process: (i) noticing an object (through the visual location buffer), (ii) finding what that object is, i.e., attending to the object (through the visual buffer).

The next rule start the retrieval process. The retrieval process should be simple: match the value in the chunk carried in the visual module to the retrieval module that will search the declarative memory for the same element. In the rule that follows, the crucial bits are line 7 and line 14, which ensure that the value of the seen chunk forms the basis for the retrieval of a word.

```
[py50] >>> model.productionstring(name="attend_probe", string="""
...     =g>
...     isa      goal
...     state    'attend'
...     =visual_location>
...     isa      _visuallocation
...     ?visual>
...     state    free
...     ==>
...     =g>
...     isa      goal
...     state    'retrieving'
...     +visual>
...     isa      _visual
...     cmd      move_attention
...     screen_pos =visual_location
...     ~visual_location>""")
{'=g': goal(state= attend), '?visual': {'state': 'free'}, '=visual_location': _visuallocation(cc
==>
{'=g': goal(state= retrieving), '+visual': _visual(cmd= move_attention, color= , screen_pos= vi
```

The last two rules are specified below. They consider two possibilities: (i) a chunk was retrieved (the first rule), (ii) no chunk was found (the second rule). The rules should look familiar, the only new bits are lines 12 – 15 and 45 – 48. These lines set the motor module in action. The motor module is there only to carry out a task, which is done using the special chunk key. The chunk has two slots: *realtime* (what command should be carried out) and *gui* (what key should be pressed).

```
[py51] >>> model.productionstring(name="recalling", string="""
...     =g>
...     isa      goal
...     state    'retrieving'
...     =visual>
...     isa      _visual
...     value    =val
...     ==>
...     =g>
...     isa      goal
...     state    'retrieval_done'
...     +retrieval>
...     isa      word
```

```

...     form      =val"")
{'=g': goal(state= retrieving), '=visual': _visual(cmd= , color= , screen_pos= , value= =val)}
==>
{'=g': goal(state= retrieval_done), '+retrieval': word(form= =val)}

```

Before we run the simulation of the model, we have to specify one last bit: what should appear on the screen. We use a dictionary data structure for that. The dictionary data structure is represented using {} brackets and it consists of key-value pairs. Values can themselves be dictionaries.

```

[py52] >>> model.productionstring(name="can_recall", string="""
...     =g>
...     isa      goal
...     state    'retrieval_done'

...     key      'F',"")
{'=g': goal(state= retrieval_done), '?retrieval': {'buffer': 'empty', 'state': 'error'}}
==>
{'=g': goal(state= done), '+manual': _manual(cmd= press_key, key= F)}

```

We specify here that our first (and only) stimulus is printing the word *elephant* in the position 320x180 pixels.

Initializing the simulation is done below.

```
[py53] >>> word = {1: {'text': 'elephant', 'position': (320, 180)}}
```

1

Unlike in the last chapter, we now call the simulation with various arguments. The first argument (`True`) states that the simulation should proceed in real time. `Environment` specifies whether a graphical user interface (a separate window) should be started to represent the environment (this option is switched off here, but by all means, switch it on on your computer by setting the argument to `stimuli`). The third argument states what environment process should appear in our environment. You could in principle create your own but there is one predefined in the class `triggers`. This will print stimuli and after a specific time elapses or the right trigger is pressed, it will remove the stimulus and print a new one (or end). The following three arguments (`times`, `word` and `run`) specify values in the environment process. The first one states what stimuli should be printed. In our case, this will be the word *elephant*, as specified in the variable `move_attention`. The second one states what triggers the process should respond to (we assume that it should not respond to anything). The last argument states how long the stimulus should be printed (1 s).

We run the simulation using the method `??`.

```
[py54] >>> sim = model.simulation(realtime=True, gui=False, environment_process=environment.environment)
```

Let us first consider the general picture this trace paints. In this model, we see that it should take roughly 450 ms to find a stimulus, decide whether it is a word and to press the right key (check the event 'KEY PRESSED'). This is slightly faster than 500-600 ms usually found in lexical decision tasks (Forster, 1990a; Murray and Forster, 2004). But notice that while we model eye movement and finger movement in quite some detail, we completely abstract away from memory retrieval. The retrieval always takes 50 ms regardless of any parameter of the word. This is definitely not correct. We will improve the state of affairs in the next chapter.

Before going there, we notice that there are a few new things in the trace of the model. They represent the visual model and the motor model. The events of the first model are signalled by the name 'visual' and they simulate attention to a visual object. The events of the second model appear under the name of 'motor'. What do they mean? We will explain that in the next two sections.

2.12.4 Vision in ACT-R

Traditionally, it has been assumed that attention corresponds to the focus position of eyes (see, e.g., Just and Carpenter 1980; Just et al. 1982), so to understand what one attends it suffices to look at one's eye positions. But this is too simplistic. In reading, it is known that some words (especially high-frequent ones) are processed without ever receiving eye focus (Schilling et al., 1998; Rayner, 1998, a.o.). The EMMA model captures this by disassociating eye focus and attention: the two processes are related but not identical.

A shift of attention to a visual object (the command `??`) triggers an immediate attempt to encode the object as an internal representation. At the same time, it also triggers eye movement. However, the two processes proceed independently of each other.

The time needed to encode an object, t_{enc} is modeled using a gamma distribution as follows:

$$(4) \quad t_{enc} \approx \text{Gamma}(\text{shape} = T_{enc}, \text{scale} = T_{enc}/9)$$

That is, it is the gamma distribution with mean T_{enc} and the standard deviation $\frac{T_{enc}}{3}$. The parameter T_{enc} is found using the following formula:

$$(5) \quad T_{enc} = Ke^{kd}$$

Where:

- d is a distance between the current focal point of the eyes and the object to be encoded, measured in degrees of visual angle
- k is a free parameter, scaling the effect of distance (it is set at 1 by default)
- K is a free parameter, scaling the encoding time itself (set at 0.01 by default)

The time needed to shift eyes to the new object is split into two sub-processes: preparation and execution. The preparation is modeled as a gamma distribution with mean 135 ms and standard deviation 45 ms. The execution, which follows the preparation, is modeled as a gamma distribution with mean 70 ms + 2 ms for every degree of visual angle between the current eye position and the targeted visual object, and standard deviation one third of the mean. It is only at the end of the execution that eyes focus the new position. Thus, the whole process of eye movement takes around 200 ms, which corresponds to average saccade latencies reported in previous studies (see, e.g., [Fuchs 1971](#)).

In the trace of the model, [py54], the time point of encoding a visual object is signalled by the event 'ENCODED VIS OBJECT'. The end of the preparation phase is signalled by 'PREPARATION TO SHIFT VISUAL ATTENTION COMPLETED'. The end of the execution shift is signalled by 'SHIFT COMPLETE TO POSITION'. It is only at the last event that eyes end up at the new location, but the internal representation of the object has been encoded for a long time at this point as you can check, so cognitive processes had time to proceed while eyes were moving to a new position.

How do visual encoding and eye movements interact? Three options could take place. First, encoding could be done before the end of the preparation phase. (This is the case here.) If the following cognitive processes are rapid enough to cancel eye movement or request a new position before the end of the preparation phase, eye shift is interrupted. (This is not the case here, hence eye shift is carried out.) Second, encoding could be finished during the execution phase. At that point, eye movement cannot be stopped any more. Finally, it could happen that visual encoding is still not done after eyes shift to a new position. In that case encoding is re-started. Given the original time needed to encode, t_{enc} , and the time completed in the original encoding, t_c , and the new encoding time, t'_{enc} , the new time to encode is calculated as:

$$(6) \quad t = (1 - (t_c/t_{enc})) * t'_{enc}$$

Since the eye position is now closer to the object, the new process should proceed faster and it is furthermore decreased by the amount of encoding that was already achieved.

2.12.5 Manual processes in ACT-R

Similarly to the vision module, the motor module is split in several sub-phases when carrying out a command: the preparation phase, the initiation phase, the actual key press and finishing the movement (returning to the original position). As in the case of the visual module, cognitive processes can interrupt a movement, but only during the preparation phase. The time needed to carry out every phase is dependent on several variables:

[py1] Is this the first movement or not? If something was pressed before, was it pressed with the same hand or not? Answers to these questions influence the amount of time the preparation phase takes.

[py2] Is the key to be pressed on the home row or not? The answer to this question influences the amount of time the actual movement requires, as well as the preparation phase.

TODO - bottom up parser; the code for that has to be cleaned up because of changes to pyactr since the last time

2.12.6 Exercises

Exercise 1

In our model, visual object encoding was faster than the preparation of the eye shift. Try to get the encoding follow the preparation phase and the execution phase. You could do that in two ways: (i) by changing the position of the object and/or the original focus position; (ii) by changing the parameters related to visual encoding (`eye_mvt_angle_parameter` and/or `eye_mvt_scaling_parameter`); these parameters are specified when initializing an ACT-R model, e.g., by stating:

```
[py55] >>> sim.run(2)
(0, 'PROCEDURAL', 'CONFLICT RESOLUTION')
(0, 'PROCEDURAL', 'RULE SELECTED: find_word')
****Environment: {1: {'text': 'elephant', 'position': (320, 180)}}

(1, 'PROCEDURAL', 'CONFLICT RESOLUTION') 53
(1, 'PROCEDURAL', 'NO RULE FOUND') 54

```

Exercise 2

In the model, only one stimulus was used. But in experiments, it is standard that many stimuli follow each other. Recode the model so it could simulate lexical decision on two (or more) stimuli following each other (e.g., find the word, recall the word, press the key, wait for the next stimulus etc.). In order to test the model, you'll also need to change the stimuli you use in your environment. They should look as follows:

```

[py56] >>> actr.ACTRModel(environment=environment,\ 1
...     automatic_visual_search=False, eye_mvt_angle_parameter=10) 2
<pyactr.model.ACTRModel object at 0x7f0e5a592828> 3

```

To break this down, multiple stimuli are written as a list (enclosed in the [] brackets) and each element in the list is one stimulus, appearing on a screen for the amount of time given when starting simulation.

Appendix: The agreement model

File `ch2_agreement.py`:

```

"""
